

# NEOPHOBIA

John Collins

**Abstract:** L. A. Paul argues that epistemically transformative choice poses a special problem for standard theories of decision: when values of outcomes cannot be known in advance, deliberation cannot even get started. A standard response to this is to represent ignorance of the nature of an experience as uncertainty about its utility. Assign subjective probabilities over the range of possible utilities it may have, and an expected utility for the outcome can be figured despite the agent's ignorance of its nature. But this response to Paul's challenge seems inadequate. Decision theory should leave conceptual room for rational neophobia. A decision theory like Isaac Levi's, which allows for indeterminacy in utility, might accommodate the phenomenon. Levi's discussion of indeterminate utility has focused on examples of risk aversion like the Allais problem and on situations in which there are conflicts of value. Cases of unknowable value arising in transformative choice problems might be handled similarly.

L. A. Paul defines a transformative experience to be one which is both epistemically transformative and personally transformative. An experience is epistemically transformative when there is no way of knowing in advance what the experience will be like, because actually having the experience is the only way of coming to know what it is like. An experience is personally transformative when it is "life-changing in that it changes what it is like to be you, that is, it changes your point of view, and by extension, your personal or subjective preferences" (2015, 16).

Paul argues that such experiences "constitute a class of experiences that raise a special problem for rational decision-making" (2015, 17). And in fact this seems straightforwardly to be the case. Suppose that one is deliberating about whether or not to undergo a transformative experience. Following Paul, let's call such a decision problem a transformative choice problem. Then you are deliberating about what sort of person to become in the future, and in particular you are deliberating about what sort of preferences your future self should have. But some of these possible future preferences might be quite different from your present preferences. They might disagree with your present preferences in various ways. In fact they

1 might conflict with your present preferences on the very question of whether  
 2 it is good to be, or to become, a person with such preferences. In such  
 3 a case, where there is a clash between prior- and envisaged post-choice  
 4 preferences, it is far from clear which should rationally prevail. That is,  
 5 it doesn't seem right to say that such conversions can always be justified  
 6 *ex post facto* from one's transformed point of view. After all, the person  
 7 one has become might have views that from one's former standpoint seem  
 8 completely reprehensible. But neither does it seem correct to say that one's  
 9 prior preferences should always win out either. Mightn't there be genuine  
 10 cases of enlightenment where your later self thinks quite rightly: I'm a better  
 11 person now for having undergone that change? And mightn't one add: And  
 12 I'm better in ways that I simply wouldn't have appreciated beforehand?

13 For those reasons I think that Paul is absolutely correct in thinking that  
 14 standard accounts of rational decision-making have a deep difficulty in  
 15 accounting for choices concerning personally transformative experience.

16 My interest here, however, is with a parallel problem for decision theory  
 17 that Paul sees as arising in decision problems involving options that are  
 18 merely epistemically transformative, like, for example, the decision whether  
 19 or not to try a new and unfamiliar type of food. This forms one of the  
 20 major threads running through Chapter 2 of her book, the chapter entitled:  
 21 "Transformative Choice." I find Paul's argument curiously compelling but  
 22 also quite elusive. It is my aim in the present paper to explain what I find  
 23 difficult about Paul's line of thought about epistemically transformative  
 24 decision problems, and also to attempt to explain why, even when certain  
 25 distracting side issues are cleared up, there remains a significant core truth  
 26 here that Paul is sensitive to. I would like to try to display that truth in a  
 27 way that is free from what to my mind are the distracting side issues.

28 Paul writes:

29 The key to understanding the problem that transformative  
 30 experience raises is to recognize that the standard models  
 31 for ignorance can only function if they can represent the  
 32 structure of the value space of the outcomes for a decision  
 33 problem. . . .

34 As a result, in order to use these models for a decision  
 35 made under conditions of ignorance, *you must be able to*  
 36 *know the values of the of the relevant outcomes.* You do  
 37 not need to know the probabilities that the outcomes, given  
 38 the acts, will occur, but you do need to know how to value  
 39 the relevant outcomes. A way to put this is that you must  
 40 be able to describe the state space of your outcomes, and  
 41 you must have a suitably defined value function for these  
 42 outcomes. If you cannot know the values of the relevant  
 43 outcome or if the values are not yet determined, so that  
 44 you cannot describe the state space or assign values that  
 45  
 46

1 will remain constant to outcomes, you do not have the  
 2 information you need to use these types of models to rep-  
 3 resent your decision. For without an adequate description  
 4 of the space and without a suitable defined value function  
 5 for the outcomes, you cannot know if the structure of any  
 6 particular model adequately represents the structure of the  
 7 actual situation. (2015, 30–31)

8 We might summarize the line of argument like this. Deliberation cannot  
 9 even get started unless the decision maker knows the values of the possible  
 10 outcomes. When options are epistemically transformative, their values  
 11 cannot be known in advance. Hence in epistemically transformative choice  
 12 problems deliberation cannot get started.

13 There's a picture of decision making behind all this that we might call  
 14 the simulation model of deliberation. In other passages Paul is quite explicit  
 15 about this picture:

16  
 17 When you are considering your options, you evaluate each  
 18 possible act and its experiential outcomes by imagining  
 19 or running a mental simulation of what it would be like,  
 20 should you act, for each relevant possible outcome of each  
 21 relevant act. You simulate the relevant possible outcomes  
 22 for yourself, that is, you simulate what it would be like for  
 23 you to have each of these experiences.

24 After you run each cognitive simulation, you assign  
 25 each outcome a subjective value. . . . [O]nce you've  
 26 determined the overall subjective value of each outcome,  
 27 you can compare the expected values of different possible  
 28 acts to determine which one you should perform. (2015,  
 29 26–27)

30 This simulation model of deliberation assumes what Philip Pettit has  
 31 called the idea of decision theory as a *calculus* for decision making (1991).  
 32 In order to understand this idea, we shall need to focus a little on the details  
 33 of the standard theory.

34 Common to all the standard accounts of decision theory is the idea  
 35 that rational choice is choice that maximizes expected value. The agent is  
 36 supposed to have a subjective probability function that assigns credences to  
 37 all the various possible states of the world, and a subjective utility function  
 38 that assigns real number values to possible outcomes. This utility function  
 39 is only unique up to positive affine transformation, in other words both the  
 40 choice of unit size, and the location of the zero point are arbitrary. (This  
 41 kind of scale dependence is familiar to us from the case of temperature  
 42 measurement. Degrees Fahrenheit can be obtained from degrees Celsius by  
 43 the following affine transformation: multiply by 9/5 and add 32.)

44 Then the expected value of each of the agent's options can be calculated  
 45 as a credence-weighted average of the utilities of each of the possible  
 46

1 outcomes of that option. The picture of decision theory as a calculus  
 2 for decision-making is the natural idea that the process of deliberation  
 3 mimics this formalism; it is the idea that when a rational decision-maker  
 4 deliberates, she engages in something like this calculation of expected  
 5 utilities as subjective probability weighted averages of the utilities of the  
 6 possible outcomes, where the utilities of the individual outcomes have been  
 7 arrived at prior to all this by the method of mental simulation.

8 If this is one's picture of rational deliberation, then it is difficult not to  
 9 agree with Paul's claim that deliberation cannot even get started unless the  
 10 decision-maker already knows the values of outcomes.

11 This picture of rational deliberation goes hand-in-hand with a *psycho-*  
 12 *logical realism* about utility and credence. (See, e.g., [Buchak 2013](#), 17.)  
 13 According to the psychological realist, utility and credence are real mental  
 14 states. Think of them as degrees of desire and degrees of belief respectively.

15 For present purposes I'm happy to assume this realist picture. But it  
 16 will be useful for our purposes to follow Jamie Dreier in drawing a further  
 17 distinction between two kinds of psychological realism about utility and  
 18 credence. (See [Dreier 1996](#) and [Buchak 2013](#), 17–18.) Let's focus on  
 19 the case of utility. Dreier distinguishes between a *constructive* and a *non-*  
 20 *constructive realism* about utility. At issue is whether or not facts about an  
 21 agent's utilities go beyond the facts about the agent's preferences between  
 22 options. The constructive realist is someone who believes that they do not.  
 23 According to the constructive realist, all the facts about the agent's utility  
 24 function supervene on the facts about her preferences. So, for example: the  
 25 fact that outcome *y* lies exactly halfway between outcomes *x* and *z* on the  
 26 agent's utility scale is simply the fact that the agent is indifferent between *y*  
 27 and a gamble that gives her a fifty percent chance of outcome *x* and a fifty  
 28 percent chance of outcome *z*. For the constructive realist, such facts about  
 29 preference are constitutive of what it is to have a particular utility function.

30 A non-constructive realist, on the other hand, thinks that it is possible,  
 31 in principle, for there to be facts about the utility function that outstrip  
 32 the facts about what the agent prefers. So according to a non-constructive  
 33 realist about utility, it might be possible, for example, to access the facts  
 34 about one's own utility function by direct introspection, or, perhaps, by the  
 35 method of mental simulation of outcomes that Paul describes.

36 Now Paul notes that “for simplicity” she is “assuming a version of  
 37 ‘non-constructive realism’” ([2015](#), 21, fn. 25). But it seems to me that this  
 38 assumption is not at all an innocent one for the purposes of simplification  
 39 only as the footnote suggests. In fact it seems to me that it is only on the as-  
 40 sumption of a non-constructive realism about utility that her “deliberation  
 41 cannot even get started” argument can be made to seem at all plausible.

42 Suppose that one adopts a constructive realism about utility. Then the  
 43 whole idea of direct access to one's utilities for outcomes via introspection  
 44 and mental simulation will seem completely implausible. In fact the whole  
 45  
 46

1 idea of decision theory as a calculus for decision making will seem mis-  
 2 guided. For the constructive realist, decision theory will be better viewed as  
 3 what Pettit calls as a *canon* rather than a calculus for good decision making.  
 4 For the constructive realist, preference is conceptually prior to utility. Any  
 5 agent whose preferences are coherent in the sense that they satisfy the  
 6 axioms of formal decision theory can be seen as choosing rationally so as to  
 7 maximize expected utility, that is, so as to best serve her desires according  
 8 to her beliefs, where those desires and beliefs, construed as admitting of  
 9 degree, are quite real, but are nothing over and above that coherent pattern  
 10 of preference to which she is disposed.

11 From this viewpoint it seems quite clear what the decision theorist should  
 12 say about cases of epistemically transformative choice. Since it is impossible  
 13 to know what an outcome of such a choice will be like in advance of  
 14 actually having made the choice and experienced the outcome, the method  
 15 of simulation is unavailable. But so what? In such a situation an “outcome”  
 16 will in turn be a risky prospect that delivers, with subject probabilities  
 17 determined by the agent’s coherent preferences, various possible utilities if  
 18 the world turns out to be one way, or another, with respect to how it would  
 19 turn out to feel like to be the agent experiencing that outcome.

20 That the precise phenomenological character of each of these “refined”  
 21 outcomes cannot be anticipated is neither here nor there. Remember: we  
 22 are working in a decision theoretic framework according to which all that  
 23 is relevant to the rationality of an agent’s choices are the utilities she assigns  
 24 to outcomes and the credences she gives to possible states of the world.  
 25 Nothing else is relevant. In particular: further facts about the particular  
 26 phenomenological character of the outcomes are not relevant. Once one  
 27 gives up on the non-constructive realist idea that utility is conceptually  
 28 prior to preference, and thinks instead of the utility function as constructed  
 29 out of facts about coherent preference, there is nothing at all paradoxical or  
 30 puzzling about this picture of things: in-principle ignorance as to the precise  
 31 value of an outcome of an epistemically transformative choice problem  
 32 simply gets represented, in the usual and obvious way, as a gamble that  
 33 might yield any one of a range of possible utility values, depending on how  
 34 things turn out to be.

35 So far this all sounds as though I am unsympathetic to Paul’s claim that  
 36 epistemically transformative choice poses a problem for standard decision  
 37 theory. But that’s actually not the case. As I said earlier, I think there’s a  
 38 core of truth to what Paul is claiming. The rest of the paper will be devoted  
 39 to explaining one way of starting to make good on this claim. It’s offered  
 40 as a friendly amendment to the argument of the second chapter of Paul’s  
 41 book, and she is welcome to accept it or reject it as she sees fit.

42 Here’s the rough idea. Various critics of standard decision theory have  
 43 argued that decision theory is lacking in that it allows no room for a rational  
 44 aversion to risk. Similarly—I think—reflection on Paul’s epistemically  
 45 transformative choice examples might lead one to think that the standard  
 46

1 theory is impoverished in another important respect. It's impoverished  
 2 in that it leaves no conceptual room for what one might call rational  
 3 *neophobia*. Then in so far as neophobia should not be seen as irrational-  
 4 in-principle, it will follow that Paul's examples do offer a new and serious  
 5 challenge to standard accounts of rational choice.

6 'Neophobia' is a term used in the psychological literature to refer to  
 7 an abnormal fear of anything new. (Sometimes this is referred to instead  
 8 as *cainophobia* or *cainotophobia*.) One particularly common form is  
 9 food neophobia, as many parents of young children well know. Here I  
 10 will use the term in a neutral way that is not intended to suggest that  
 11 there is anything abnormal, or pathological, or irrational about this kind  
 12 of preference structure. Neither do I want to suggest that neophobia is  
 13 either more or less common than, or more or less reasonable than, the  
 14 opposing tendency: neophilia (nor, for that matter, to a *ceteris paribus*  
 15 indifference toward outcomes that are new and alien in Paul's sense of  
 16 being epistemically transformative).

17 Now let's consider what the preferences of a neophobic agent might look  
 18 like.

19 In particular, let's consider situations in which a person is confronted  
 20 with a choice problem in which one of the options has outcomes with which  
 21 she is experientially unacquainted. For the sake of simplicity I will focus  
 22 on just the kind of example that Paul introduces: a situation in which an  
 23 available option is to try some sort of food of a kind that the agent has  
 24 never previously tasted and in which it might be reasonable to think that  
 25 the experience of trying it for the first time might be radically unlike any  
 26 kind of taste experience the agent has ever had in the past. To be definite:  
 27 let's imagine that the agent, having never previously eaten durian, is now  
 28 faced with a choice situation in which one of the options is to taste it for  
 29 the very first time. For the uninitiated: durian is a kind of fruit native to  
 30 Southeast Asia. Reported opinions about it vary wildly. It has a distinctive  
 31 smell that some find pleasant, while others find completely disgusting. All  
 32 agree, however, that the distinctive aroma and taste of the durian fruit are  
 33 impossible to convey to someone who has never experienced eating it.

34 Part of the reason for choosing this kind of example is the fact that  
 35 it seems fairly safe to say, with Paul, that opting for such an outcome  
 36 will be epistemically transformative for the agent without being personally  
 37 transformative. Once I've tasted durian for the first time I'll have learned  
 38 something that I could not possibly have learned in any way other than  
 39 by actually having had the experience. But at the same time it seems fairly  
 40 safe to say, in advance, that whatever that experience turns out to be like,  
 41 it's not going to change in any deep, or important, or fundamental way,  
 42 the kind of person that I am. It's not, for example, going to result in any  
 43 change to my core values or preferences, and this is something which, in  
 44 turn, I can be fairly sure of ahead of arriving at a decision.

1 So there's the radically unknown, and unknowable option of durian, say,  
2 available on the menu. How, according to a standard theory of choice, is  
3 the agent supposed to evaluate this option?

4 The standard proposal, rehearsed earlier, is to represent the agent's  
5 ignorance about what the experience of tasting durian will be like as  
6 ignorance over a range of possible outcomes in which the experience of  
7 tasting and smelling the fruit turns out to be more or less pleasurable (or  
8 unpleasant). Now even though the particular felt qualities of the possible  
9 experiences in this range cannot be described or anticipated in advance,  
10 the idea is that that should not matter, because all of that unattainable  
11 information is going to be filtered through the lens of the agent's utility  
12 function anyway. Ultimately—so the orthodox story goes—all that is going  
13 to end up mattering to the theory of rational choice are the utilities that  
14 the agent would assign to each of those possible experiential scenarios  
15 were they to turn out to be actual. If that is correct, then the particular,  
16 and ungraspable, felt quality of various of those experiences simply falls  
17 out of the picture. The adequacy of the standard theory is defended by  
18 representing all of that ignorance as simply ignorance as to what the utility  
19 of the experience will actually turn out to be.

20 Now another reason for favoring an illustrative example of this fairly  
21 trivial sort is that it also seems fairly safe to say at this point that whatever  
22 the experience of tasting the fruit turns out to be like, its utility can be  
23 anticipated to fall within a certain range of possible values, so the agent  
24 can confidently place upper and lower bounds on how good or bad the  
25 experience will turn out to be. So let's assume that we have good evidence  
26 that enables us to set aside, for example, such possibilities as that the fruit  
27 will turn out to be poisonous, or that it will send the agent into anaphylactic  
28 shock, or that it will trigger some other kind of allergic reaction. Similarly,  
29 at the other end of the scale, let's suppose that the agent can safely assume  
30 in advance that the experience is not going to be *so good* that it will turn  
31 out to be “off the charts” in the sense of being better, and of course in  
32 an unanticipatable way, than some value set in advance as the maximum  
33 possible utility.

34 Once we have this upper and lower bound to the possible utility of the  
35 unknowable experience set, then the idea will be that we can, in principle,  
36 go about the task of constructing a kind of *synthetic lottery* over a range of  
37 quite familiar outcomes, a synthetic lottery that can then go proxy for the  
38 outcome that involves the epistemically transformative experience.

39 We need not suppose that this lottery have a continuum of possible prizes  
40 corresponding to all of the real numbers that are the possible utilities in  
41 the interval between the minimum and maximum values. We may suppose  
42 that what I'm calling the synthetic lottery has only some finite number  
43 of outcomes or prizes. The important thing, however, is that all of those  
44 outcomes must involve experiences that are quite familiar to the agent, and  
45 that the known utility of each outcome must lie somewhere on the closed  
46

1 interval between the upper and lower bounds, and that those utilities be  
 2 sufficiently well distributed, or uniformly spread, over the interval so that  
 3 whatever the epistemically transformative experience turns out to be like, it  
 4 will also turn out to have a utility, for the agent, that is very close to the  
 5 utility of one of the prizes in what I'm calling the synthetic lottery. Again:  
 6 what one means here by "very close" can simply be adjusted, if required,  
 7 by increasing the finite number of prizes.

8 We are now in a position to see what the preferences of what I'm calling  
 9 a neophobic agent might be like.

10 Suppose that an agent confronts a decision problem in which some  
 11 option *A* is epistemically transformative. Construct a synthetic lottery  
 12 corresponding to the experientially unknowable option *A* so that:

- 13 (1) For any possible utility value  $x$  that the epistemically transformative  
 14 experience may turn out to have for the agent, there is a possible  
 15 outcome to the lottery that is both (a) experientially familiar to the  
 16 agent and (b) has a utility that is (arbitrarily) close to  $x$ .
- 17 (2) The chances of the various possible outcomes to the lottery are  
 18 weighted so as to correspond to the agent's subjective probability  
 19 distribution over the range of possible utilities that the epistemi-  
 20 cally transformative option *A* may turn out to have, whatever that  
 21 subjective probability distribution happens to be.  
 22

23 Then such a synthetic lottery will have, for the agent, an expected utility  
 24 that is equal to the agent's expected utility for option *A*.

25 But now suppose that, despite this equality in expected utilities, the agent  
 26 nevertheless prefers the prospect of the synthetic lottery to the epistemically  
 27 transformative option *A*.

28 If competing explanations of the pattern have been ruled out, then the  
 29 remaining preference for the synthetic lottery over the prospect of the epis-  
 30 temically transformative experience may be taken, I think, as an indication  
 31 that the agent is neophobic. And, of course, the opposite preference pattern,  
 32 that is, a preference for the radically unfamiliar option over the correspond-  
 33 ing synthetic lottery constructed so as to have the same expected utility,  
 34 would be an indication of neophilia.

35 My feeling is that there need be nothing at all irrational about either of  
 36 these possibilities. We should have a normative theory of decision liberal  
 37 enough to allow for cases of rational neophobia. And of course the same  
 38 goes for the opposed phenomenon of rational neophilia.

39 It will be helpful here, I think, to compare what I'm calling neophobia  
 40 with other patterns of preference that orthodox decision theory cannot  
 41 accommodate and yet which seem perfectly rationally permissible. The first  
 42 kind of example I have in mind involves an agent who is averse toward risk.  
 43 Just as many have argued that a theory of decision making should allow  
 44 for the rationality of various attitudes other than indifference toward risk,  
 45  
 46

1 so—it might be argued—such a theory should be just as permissive when it  
 2 comes to attitudes other than indifference towards what is new.

3 So let's approach this task by first reviewing the problem that risk poses  
 4 for standard accounts of decision theory.

5 **Example 1: The Allais Problem.** The agent is to win a  
 6 prize determined by drawing a ticket in a fair lottery with  
 7 one hundred tickets. Consider the four options  $A_1$  to  $A_4$   
 8 displayed in the table below.  
 9

	0.01 Ticket 1	0.10 Tickets 2-11	0.89 Tickets 12-100
10 $A_1$	\$1M	\$1M	\$1M
11 $A_2$	\$0	\$5M	\$1M
12 $A_3$	\$1M	\$1M	\$0
13 $A_4$	\$0	\$5M	\$0

14 Option  $A_1$  guarantees the agent one million dollars no matter which  
 15 ticket is drawn. Option  $A_2$  is somewhat riskier: it yields five million dollars  
 16 instead of a million if a ticket numbered 2 through 11 is drawn, but it  
 17 also leaves the agent with a one percent chance of getting nothing at all.  
 18 Faced with a choice between these first two options, many agents report  
 19 a preference for  $A_1$  over  $A_2$ . Now this might be taken as evidence that  
 20 such an agent has a diminishing marginal utility for money: getting the  
 21 first million dollars makes a lot more difference than getting the next four  
 22 million dollars would. And, in fact, if the utility difference for the agent  
 23 between the outcomes Win \$1M and Win \$0 is more than ten times the  
 24 utility difference between Win \$5M and Win \$1M then a preference for  $A_1$   
 25 over  $A_2$  is exactly what expected utility theory prescribes.

26 The problem is, however, that many of those same agents—apparently  
 27 perfectly rational people, I'm one of them—also report a preference for  $A_4$   
 28 over  $A_3$ . That is, they prefer a ten percent chance of five million dollars to  
 29 an eleven percent chance of one million.

30 But now agents like us have run foul of standard expected utility theory.  
 31 For there are simply no utilities that may be assigned to the three outcomes  
 32 \$0, \$1M, \$5M that can rationalize that pair of preferences as maximizing  
 33 expected utility. The agent's preferences are in violation of Savage's Sure-  
 34 Thing Principle, one of the axioms of the standard theory. If you cover over  
 35 the third column of the table, the pattern of outcomes on what remains is  
 36 the same for  $A_1$  and  $A_2$  as it is for  $A_3$  and  $A_4$ , so the Sure-Thing Principle  
 37 requires that an agent's preference for comparison for the first pair match  
 38 that for the second.  
 39

40 What is going on here?

41 Many decision theorists, going back to Allais himself, have taken this  
 42 example to be a reductio of any normative theory of choice which rules out  
 43 as irrational the kind of aversion to risk that characterizes the preference  
 44  
 45  
 46

1 for  $A_1$  over  $A_2$  and for  $A_4$  over  $A_3$ . If these preferences express a perfectly  
 2 rational attitude toward risk, then standard expected utility theory will  
 3 have to be liberalized in some way to yield a more reasonable set of norms.

4 But how might the standard theory be adjusted to accommodate the  
 5 possibility of rational risk aversion? I will describe two possible answers  
 6 to that question in what follows. The first of these is a particularly well-  
 7 worked-out and elegant proposal due to Lara Buchak, developed and  
 8 defended in her recent book *Risk and Rationality*. I'll approach Buchak's  
 9 account via an example of the sort she uses to motivate the project in the  
 10 first chapter of the book. (The version of the example I present here is due  
 11 to Rachael Briggs.)

12 **Example 2: The Pizza Problem.** Confronted with a choice  
 13 between the following two options:

14 (A) One pizza for sure.

15 (B) A gamble that yields two pizzas if the toss of a fair  
 16 coin lands heads and nothing if the coin lands tails.

17 My friend and I share a preference for (A) over (B).  
 18

19 But now let's stipulate that the explanation of my preference for (A) over  
 20 (B) differs from that of my friend's preference for (A) over (B). In particular,  
 21 let's suppose that I prefer the certainty of one pizza to a toss-up between  
 22 two pizzas and nothing, because one pizza is just about all that I can eat.  
 23 I'm full after a single pizza, and as a result, the value I assign to getting a  
 24 single pizza lies more than half way along the interval on my utility scale  
 25 from no pizza to two pizzas. As a result of the fact that I have this kind of  
 26 diminishing marginal utility for pizza, I prefer (A) to (B).

27 Things are quite different, on the other hand, in my friend's case. My  
 28 friend, let's suppose, is insatiable. For him, the utility of the second pizza  
 29 is undiminished by the fact that he has already eaten the first. So for my  
 30 friend:

$$31 \quad U(\text{two pizzas}) - U(\text{one pizza}) = U(\text{one pizza}) - U(\text{no pizza})$$

32 Yet my friend, like me, prefers (A) to (B). Why? Because he is risk averse.  
 33 He simply does not want to take the chance of getting nothing.

34 There's another possibility here too, which I will only mention and then  
 35 set aside. An agent with an insatiable appetite for pizza might prefer (A)  
 36 to (B) out of *pessimism* rather than risk aversion. That is, the agent might  
 37 judge that the probability of the fair coin landing heads is less than one half  
 38 when his dinner depends on the outcome of the toss.

39 But let's set that further possibility aside. Let's suppose that we are  
 40 satisfied that my friend assigns subjective probability  $\frac{1}{2}$  to the coin's landing  
 41 heads, whether or not his dinner depends on the outcome, and let's suppose  
 42 further that we are satisfied that, for him, the utility of one pizza is exactly  
 43 half way between the utilities he assigns to two pizzas and that he assigns  
 44 to nothing. Then by the lights of standard decision theory, my friend's  
 45  
 46

1 preference for (A) over (B) is irrational, since, for him, the expected utilities  
 2 of (A) and (B) are equal to one another.

3 Yet—to many of us at least—this seems to be the wrong thing to say  
 4 about my friend’s preferences. To many of us it seems as though it is  
 5 perfectly rationally permissible to be averse to risk taking in this kind of  
 6 way. From this viewpoint, standard expected utility theory seems unduly  
 7 harsh or over-restrictive for deeming such patterns of preference irrational.

8 But perhaps one ought to be suspicious of what I have stipulated above  
 9 in setting out the details of this second example. By stipulating that we are  
 10 satisfied, somehow, in a way that is independent of his preference for (A)  
 11 over (B), that my friend’s subjective probability for the coin landing heads  
 12 is  $\frac{1}{2}$  and that his utility gain from the second pizza is equal to the utility  
 13 gain from the first, we might be thought to be committing ourselves to a  
 14 non-constructive realism about utility and begging the question against the  
 15 constructive realist.

16 Now, certainly, if there *are* further features of my friend’s psychological  
 17 state that we can point to and identify as those psychological features  
 18 that ground the facts about his utility function stipulated in the second  
 19 example, then that would demonstrate the inadequacy of any theory that  
 20 left no room for that possibility. But suppose that there are no such further  
 21 features to be found. Then a defender of the standard theory might simply  
 22 reply that the apparent distinction stipulated in Example 2 between my  
 23 friend’s situation and mine is really a distinction without a difference. That  
 24 is, the claim a defender of the standard theory might make is that this  
 25 apparent distinction between my friend’s situation and mine is precisely the  
 26 consequence of that incorrect, non-constructive, conception of utility.

27 This still seems wrong to me. However if the defender of the standard  
 28 theory adopts this strategy the mistake now seems to be not that a certain  
 29 rationally permissible set of preferences is being ruled out incorrectly as  
 30 irrational, but rather that the standard theory is leaving no room at all for  
 31 a preference structure that in fact is perfectly possible.

32 Buchak develops and defends a theory of *risk-weighted expected utility*  
 33 in which the choice-worthiness of an act is determined by three factors,  
 34 not two. In this risk-weighted theory, the traditional roles of subjective  
 35 probability and utility are augmented by a third factor, namely a *risk*  
 36 *function*

$$37 \quad r : [0, 1] \longrightarrow [0, 1]$$

38 that is non-decreasing and such that  $r(0) = 0$  and  $r(1) = 1$ . The function  
 39  $r$  is intended to capture the facts about an agent’s attitude to risk, and,  
 40 crucially, does so in a way that can be elicited from a pattern of preferences  
 41 that is coherent in an appropriate technical sense quite independently of  
 42 the elicitation of probability and utility.

43 In order to see how this tripartite risk-sensitive scheme works it will help  
 44 first of all to reformulate the standard account of expected utility in a kind  
 45

1 of stepwise fashion that proceeds from an initial monotonic rank-ordering  
 2 of outcomes from worst to best.

3 The most general case need not detain us here. The basic idea can be  
 4 grasped by looking at a simple case where there are two possible states of  
 5 the world  $s$  and  $t$  and two possible outcomes  $x$  and  $y$  ordered so that the  
 6 latter is at least as good as the former.

7 In that case the standard expression for the expected utility of an option  
 8  $f = \{s, x ; t, y\}$ , that is, of the act that delivers outcome  $x$  in state  $s$  and  
 9 outcome  $y$  in state  $t$  is:

$$10 \quad \text{SEU}(f) = p(s).U(x) + p(t).U(y)$$

11 which, since  $x, y$  have been listed in order of increasing goodness, can be  
 12 re-written in stepwise fashion as:

$$13 \quad \text{SEU}(f) = U(x) + p(t)(U(y) - U(x))$$

14 Now that we have this equivalent step-wise reformulation of standard  
 15 expected utility, we can adjust it, via the risk function as follows to obtain  
 16 Buchak's risk-weighted expected utility REU.

$$17 \quad \text{REU}(f) = U(x) + r(p(t)).(U(y) - U(x))$$

18 To get a sense of how this works, let's see how it might be applied to  
 19 make sense of the distinction between my attitude and my friend's attitude  
 20 toward pizza in Example 2 above.

21 Here the two relevant states of the world are  $H$  and  $T$ , the two possible  
 22 results of the toss of the fair coin, and the outcomes, ranked for both of us  
 23 in order from worst to best are no pizza, one pizza, two pizzas.

24 Then the previously mentioned distinction between my friend's risk  
 25 aversion and insatiable desire for pizza, and my own risk neutrality and  
 26 diminishing marginal utility for pizza can be captured by, for example, the  
 27 assumption that my utility function for pizza is  $U_1$  where

$$28 \quad U_1(n) = \sqrt{(2n)}/2$$

29 where  $n$  is the number of pizzas received, while my friend's utility function  
 30 is

$$31 \quad U_2(n) = n$$

32 And, furthermore, my risk function  $r_1$  is the identity function

$$33 \quad r_1(x) = x$$

34 while my friend's risk function is

$$35 \quad r_2(x) = x^2$$

36 Note that for both of us:

$$37 \quad p(H) = p(T) = 1/2$$

1 since he and I agree that the coin is a fair one.

2 Plugging these utility and risk functions into the expression for risk-  
3 weighted expected utility we see that for me the value of the gamble  $g$  that  
4 delivers nothing on heads and two pizzas on tails is:

$$5 \quad \text{REU}(g) = 0 + r_1(p(T)) \cdot (U_1(\text{two pizzas}) - U_1(\text{no pizza}))$$

6 in other words:

$$7 \quad \text{REU}(g) = 0 + 1/2 \cdot (1 - 0) = 1/2$$

8 and this is less than the utility I assign to receiving a single pizza, that is,

$$9 \quad U_1(1) = \sqrt{2}/2 \approx 0.707.$$

10 For my friend, on the other hand:

$$11 \quad \text{REU}(g) = 0 + r_2(p(T)) \cdot (U_2(\text{two pizzas}) - U_2(\text{no pizza}))$$

12 and so for him:

$$13 \quad \text{REU}(g) = 0 + 1/4 \cdot (2 - 0) = 1/2$$

14 which is less than the utility he assigns to getting a single pizza, that is,  
15  $U_2(1) = 1$ .

16 This indeed has the required result that both of us prefer one pizza for  
17 sure to the gamble that gives us a 50% chance of two and a 50% chance of  
18 nothing. But that pattern of preferences has a quite different explanation  
19 in his case, where it is due to risk aversion, and in my case, where it stems  
20 from my diminishing marginal utility for pizza.

21 An appropriately chosen risk function can similarly rationalize the char-  
22 acteristic pattern of preferences in the Allais problem.

23 However, there is another kind of example that raises a similar challenge  
24 to standard decision theory, and which also cannot be accommodated in  
25 Buchak's system. The problem is due to Daniel Ellsberg and it turns out, I  
26 think, to be even more helpful to us than the first two examples in seeing  
27 how the possibility of rational neophobia might be treated formally (1961).

28 **Example 3: The Ellsberg Problem.** An urn contains balls  
29 of three colors: red, black, and yellow. You know that  
30 it contains exactly thirty red balls and that there are an  
31 additional sixty balls which are either black or yellow, but  
32 in a ratio that is not known to you. You are asked to  
33 compare first the pair of options  $E_1$  and  $E_2$  the outcomes  
34 of which are determined by the color of a ball drawn at  
35 random from the urn, as specified in the table below.

	Red	Black	Yellow
$E_1$	\$100	\$0	\$0
$E_2$	\$0	\$100	\$0
$E_3$	\$100	\$0	\$100
$E_4$	\$0	\$100	\$100

1 Then you are asked to compare option  $E_3$  to option  $E_4$ . As was the case in  
 2 the Allais example above, many apparently perfectly rational agents express  
 3 a preference for  $E_1$  over  $E_2$ , and for  $E_4$  over  $E_3$ , despite the fact that there is  
 4 no standard expected utility representation of that pair of preferences. The  
 5 situation is strikingly similar to the Allais case in that once again we have a  
 6 violation of Savage’s Sure-Thing Principle: cover over the third column of  
 7 outcomes on “Yellow,” and the pattern of outcomes on what remains is  
 8 the same for  $E_1$  and  $E_2$  as it is for  $E_3$  and  $E_4$ .

9 But there the similarities end. Strikingly, the risk-weighted utility theory  
 10 of Buchak cannot accommodate the rationality of the Ellsberg preferences,  
 11 although as we have seen her account can deal perfectly well with the Allais  
 12 phenomenon. This difference arises because Buchak drops the Sure-Thing  
 13 Principle in her axiomatization of preference; part of its work gets down  
 14 by an axiom she calls Strong Comparative Probability, and it is the Strong  
 15 Comparative Probability axiom that separates the Allais and the Ellsberg  
 16 problems. The Allais preferences satisfy it; the Ellsberg preferences do not.  
 17 (For details see Buchak 2013, 98–100, and Machina and Schmeidler 1992,  
 18 762–763.)

19 The moral of all this seems to be that the pattern of preferences com-  
 20 monly elicited by the Ellsberg example should be seen as an expression not  
 21 of an aversion to risk, but rather of an aversion to what Ellsberg called  
 22 *ambiguity*. It seems as though what leads to the choice of  $E_1$  over  $E_2$ , and  
 23 the choice of  $E_4$  over  $E_3$ , is a preference for gambling on options where the  
 24 outcomes have known objective probabilities, rather than options where  
 25 the situation is “ambiguous” in the sense that the agent does not know  
 26 what the objective probabilities are.

27 Now Isaac Levi is a prominent example of a decision theorist who  
 28 has argued that the Ellsberg preferences should be regarded as perfectly  
 29 rationally permissible, and that the way to accommodate them in a formal  
 30 theory of decision is to allow that an agent’s subjective probabilities, that  
 31 is, her degrees of belief, may be *indeterminate* (1986).

32 In Levi’s account, an indeterminate belief state is represented not by  
 33 a single sharp subjective probability function, but by a convex set  $P$  of  
 34 probability functions. (To say that the set is “convex” is to say that  
 35 whenever  $p$  and  $q$  are probability functions in  $P$ , then every mixture  
 36  $\alpha.p + (1 - \alpha).q$ , where  $0 < \alpha < 1$ , is also a probability function in  $P$ .)

37 There are various different ways in which such indeterminate proba-  
 38 bilities might figure in a formal decision rule. Here we will follow Levi’s  
 39 suggestion that the agent first reduce the set of available options to those  
 40 that are *E-admissible*.

41 **Definition:** If an agent’s utility function is  $u$  and her inde-  
 42 terminate belief state is represented by the convex set  $P$   
 43 of probability functions, then an option  $A$  is *E-admissible* for  
 44 the agent if and only if there exists a probability function  
 45  
 46

1  $p \in P$  such that  $A$  has maximal expected utility among all  
 2 her options when those expected utilities are calculated  
 3 using  $p$  and  $u$ .

4 In the Ellsberg example the agent's indeterminate belief state is repre-  
 5 sented by the set of all probability functions that assign probability  $1/3$  to  
 6 Red, probability  $x$  to Black where  $0 \leq x \leq 2/3$  (and a multiple of  $1/60$ ),  
 7 and probability  $2/3 - x$  to Yellow. With these indeterminate degrees of  
 8 belief, both elements of the option set  $\{E_1, E_2\}$  are E-admissible in Levi's  
 9 sense. If  $p$  is chosen from  $P$  so that  $x = p(\text{Black}) \leq 1/3$  then option  $E_1$  has  
 10 maximal expected value. For any other choice of  $p$  the option  $E_2$  achieves  
 11 the maximum. So either may be chosen. We can see similarly that both  
 12 elements of the option set  $\{E_3, E_4\}$  are E-admissible.

13 We could leave it at that, or we could follow Levi in allowing that some  
 14 second-round rule of choice be applied to further winnow down the options  
 15 that have survived the first-round test of E-admissibility. For example, if the  
 16 agent adopts the rule of choosing the option from the E-admissible set that  
 17 has the highest "security level," that is, the maximin expected utility over  
 18 all  $p \in P$ , then the agent will indeed choose  $E_1$  over  $E_2$  and  $E_4$  over  $E_3$ . The  
 19 security levels for the four options  $E_1$ - $E_4$  in that order are  $100/3, 0, 100/3,$   
 20 and  $200/3$  respectively (taking the utility of money for the agent to be given  
 21 by function  $u(\$n) = n$ .)

22 Now Levi also maintains that an agent's utilities might also be inde-  
 23 terminate, and this allows him to give a similar account of the rational  
 24 permissibility of the Allais preferences.

25 We allow, that is, that an agent's utilities for outcomes be given by  
 26 a convex set  $U$  of determinate utility functions. Since there is already  
 27 a "choice of scale" indeterminacy in measuring utility—we noted earlier  
 28 the fact that utilities, like temperatures, will only ever be unique up to a  
 29 choice of zero point and unit—let's assume that there is a pair of options  
 30  $x, y$  between which the agent is not determinately indifferent and that are  
 31 ranked in the same order,  $y$  preferred to  $x$  say, by every utility function in  
 32 the agent's set  $U$ . Then we may "normalize" the set  $U$  by choosing the  
 33 scale for each of its elements  $u$  so that  $u(x) = 0$  and  $u(y) = 1$

34 The earlier definition of E-admissibility is then naturally extended to this  
 35 system that allows indeterminacy in both probability and utility:

36  
 37 **Definition:** If an agent's indeterminate belief state is repre-  
 38 sented by the convex set  $P$  of probability functions, and  
 39 her indeterminate value state by a normalized convex set of  
 40 utility functions, then an option  $A$  is *E-admissible* for the  
 41 agent if and only if there exists some probability function  
 42  $p \in P$  and some utility function  $u \in U$  such that  $A$  has  
 43 maximal expected utility among all her options when those  
 44 expected utilities are calculated using  $p$  and  $u$ .

1 The application of this idea to the Allais problem is quite straightforward.  
 2 The agent determinately ranks \$0 below \$1M, which is in turn ranked  
 3 below \$5M. We may choose \$0 and \$1M as the outcomes with respect  
 4 to which all the utility functions in the set  $U$  are normalized, by setting  
 5  $u(\$0) = 0$  and  $u(\$1M) = 1$  for all  $u \in U$ . Suppose that the agent's value  
 6 state is then represented by a convex set  $U$  of utility functions such that for  
 7 some  $u \in U : u(\$5M) < 1.1$  and for some other  $u' \in U : u'(\$5M) > 1.1$ . Then  
 8 for such an agent the characteristic Allais preferences will be rationally  
 9 permitted, since each of  $A_1, A_2$  will be E-admissible choices from the set  
 10  $\{A_1, A_2\}$  and each of  $A_3, A_4$  will be E-admissible choices from the set  $\{A_3, A_4\}$ .  
 11 And an agent who adopts, for example, the second-round rule of choosing  
 12 from among the E-admissible options the one whose second-worst outcome  
 13 is best, will consider the characteristic Allais preferences to be the uniquely  
 14 rational ones.

15 I think we should accommodate the possibility of rational neophobia in  
 16 exactly the same way that Levi treats the Allais problem. That is, I think  
 17 we should approach it as a phenomenon that can arise when an agent has  
 18 indeterminate utilities for certain outcomes. Faced with a choice problem  
 19 involving an epistemically transformative option, an agent can find herself  
 20 with no determinate attitude toward the goodness of that outcome, with no  
 21 determinate utility for it. The situation is not one which resolves itself into  
 22 an uncertainty over which of some set of more fine-grained sub-outcomes is  
 23 true. It's simply a matter of a basic and irresolvable indeterminacy. That's  
 24 why the orthodox decision theorist's suggestion that we elicit her utility  
 25 for the transformative outcome by the method of constructing a synthetic  
 26 lottery need not always work. It's not possible to elicit a sharp determinate  
 27 value for the utility of an outcome when it is just a fact that no such unique  
 28 value exists. The synthetic lottery may yield some unique number, but so  
 29 what? It's providing an answer to a different question.

30 If the agent simply has no determinate utility for an outcome  $X$  because  
 31 she is phenomenologically unacquainted with outcomes of that type, then  
 32 she may recognize that both the outcome  $X$  and its synthetic lottery "equiv-  
 33 alent" are E-admissible options. And then she might rationally opt for the  
 34 synthetic lottery over the unknown outcome because she adopts a second-  
 35 round rule of preferring the familiar to the unknown. This is a neophobic  
 36 preference structure, and it should not be ruled out by a normative theory  
 37 of choice as irrational. So we should admit indeterminacy in utility, and we  
 38 should allow for the possibility of rational neophobia.

39 Indeterminacy of utility can arise in various ways. One variety in which  
 40 Levi has been particularly interested throughout his career is the kind of  
 41 indeterminacy that stems from a conflict in values. An agent may recognize  
 42 that two different and perhaps competing features of an outcome are  
 43 relevant to establishing its utility. The agent may know that the utility of  
 44 the outcome is to be figured as a tradeoff between these competing criteria—  
 45 as some weighted mixture of the simple determinate utilities that would be  
 46

1 arrived at if only one or the other of the two factors were relevant. And yet  
 2 the agent may be forced to admit that there is no fact of matter as to how  
 3 the weighting of that mixture should get done. In such a situation the agent  
 4 will assign no determinate utility to the outcome. The best she may be able  
 5 to do is to assign it some interval of real-number values parametrized by  
 6 the possible values of the weighting factor.

7 In some of the most fascinating, and elusive, passages of Chapter 2 of  
 8 her book, L. A. Paul seems to be pushing just this kind of point. I have  
 9 in mind those passages in which, for example, she stresses the richness  
 10 and multi-dimensionality of the notion of value. To take that kind of  
 11 criticism seriously might seem to be to reject the standard decision theoretic  
 12 framework in a rather drastic and fundamental way. It might seem to  
 13 require rejecting the very idea that rationality of choice could depend  
 14 simply on facts about expected utility. I've previously resisted that idea  
 15 strongly and argued it at length with L. A. Paul. But it now seems to me  
 16 that the required revision to the standard theory need not be so drastic, and  
 17 that the means for handling her cases of epistemically transformative choice  
 18 are already well known from the work of Isaac Levi and others and might  
 19 already be required to handle other well-known problems. That's how I  
 20 now read those fascinating and elusive passages of the second chapter of  
 21 Paul's book. I've come to see her discussion of epistemically transformative  
 22 choice problems as identifying a new and very important role for the theory  
 23 of indeterminate utility. It's one more reason to be grateful to Paul for  
 24 having written such a rich and interesting book.
